A B S T R A C T

This paper is concerned with the numerical solution of large scale Sylvester equations $AX - XB = C$, Lyapunov equations as a special case in particular included, with $C$ having very small rank. For stable Lyapunov equations, Penzl (2000) [22] and Li and White (2002) [20] demonstrated that the so-called Cholesky factor ADI method with decent shift parameters can be very effective. In this paper we present a generalization of the Cholesky factor ADI method for Sylvester equations. ***An easily implementable extension of Penz's shift strategy for the Lyapunov equation is presented for the current case. It is demonstrated that Galerkin projection via ADI subspaces often produces much more accurate solutions than ADI solutions.***

## 1. Introduction

An $m \times n$ Sylvester equation takes the form

$$AX - XB = C, \tag{1.1}$$

where $A$, $B$, and $C$ are $m \times m$, $n \times n$, and $m \times n$, respectively, and the unknown matrix $X$ is $m \times n$. A Lyapunov equation is a special case with $m = n$, $B = -A^*$, and $C = C^*$, where the star superscript denotes complex conjugation and transposition. Eq. (1.1) has a unique solution if and only if $A$ and $B$ have no common eigenvalues, see, e.g., [1], which will be assumed throughout this paper.

Sylvester equations appear frequently in many areas of applied mathematics, both theoretically and practically. We refer the reader to the elegant survey in [2] and the references therein for a history of the equation and many interesting and important theoretical results. Sylvester equations play vital roles in a number of applications such as matrix eigen-decompositions [3], control theory [4], model reduction [5–7], numerical solution of matrix differential Riccati equations [8], image processing [9], and many more.

This paper is concerned with the numerical solution of Sylvester equations. Lyapunov equations as a special case are also discussed. There are several numerical algorithms for that purpose. The standard ones are the Bartels–Stewart algorithm [10] and the Hessenberg–Schur method first described in [8], but more often attributed to Golub, Nash, and Van Loan [11]. All these methods are efficient for dense matrices $A$ and $B$. However, recent interest is directed more towards large and sparse

matrices $A$ and $B$, and $C = GF^*$ with very low rank, where $G$ and $F$ have only a few columns. Applications in which the constant term $C$ naturally appears in factorized form range from optimal control [12] and image restoration [9] to model reduction based on the cross-Gramian approach [5–7]. In these cases, the standard methods are often too expensive to be practical, and iterative methods become more viable choices. Common methods for sparse $A$, $B$ are Krylov subspace based algorithms [13–17] and Alternating-Directional-Implicit (ADI) iterations [18–24]. Advantages of Krylov subspace based algorithms over ADI iterations are that no knowledge about the spectra of $A$ and $B$ is needed and (except for [17]) no linear systems of equations with (shifted) $A$ and $B$ have to be solved. But ADI iterations often enable faster convergence if (sub) optimal shifts to $A$ and $B$ can be effectively estimated. So for a problem for which linear systems with shifted $A$ and $B$ can be solved at modest cost, ADI iterations may turn out to be better alternatives. This is often true for stable Lyapunov equations from control theory [18–20,22,44].

Recently, Ding and Chen proposed a few simple iterative schemes for matrix equations in [25–27] (and others therein). The schemes, resembling the classical Jacobi and Gaussian iterations for linear systems, are easy to implement and cost little per step but converge linearly at the best. Gradient based iterative (GI) algorithms and least squares based iterative algorithms have also been proposed in [26,27,14,28,42,43] for (coupled) matrix equations, which are applicable to the Lyapunov matrix equations and Sylvester matrix equations as special cases. ADI iterations, however, achieve fast convergence rate through exploiting matrices' spectrum information.

In this paper, we shall first extend the Cholesky factor ADI for Lyapunov equations to solve Sylvester equations based on previous work in [29–31]. 'Then, we argue that often much more accurate solutions than the ADI solutions can be obtained by performing a Galerkin-type projection via the row and column subspaces of the computed solutions. The improvement is often more drastic with poor shifts. Indeed, in the absence of knowledge of the spectra, currently there is no provable way to select good shifts, and existing practices like [32,22] are more heuristic than rigorously justifiable, except for stable Lyapunov equations with Hermitian $A$ [33–35] and for Sylvester equations with Hermitian $A$ and $B$ [36].[1]

The rest of this paper is organized as follows. Section 2 reviews the ADI method and derives factored ADI iterations for Sylvester equations. An extension of Penzl's shift strategy to Sylvester equations is explained in Section 3. Projection ADI subspace methods via Galerkin projection or the minimal residual condition are presented in Section 4. Section 5 explains the connection between the new algorithm and Cholesky factor ADI for Lyapunov equations. We report several numerical tests in Section 6 and finally present our conclusions in Section 7.

*Notation.* Throughout this paper, $\mathbb{C}^{n \times m}$ is the set of all $n \times m$ complex matrices, $\mathbb{C}^n = \mathbb{C}^{n \times 1}$, and $\mathbb{C} = \mathbb{C}^1$. Similarly define $\mathbb{R}^{n \times m}$, $\mathbb{R}^n$, and $\mathbb{R}$ except replacing the word *complex* by *real*. $I_n$ (or simply $I$ if its dimension is clear from the context) is the $n \times n$ identity matrix, and $e_j$ is its $j$th column. The superscript "$\cdot^*$" denotes conjugate transposition while "$\cdot^T$" stands for transposition only. For scalars, $\bar{\alpha}$ is the complex conjugate of $\alpha$, and $\Re(\alpha)$ takes the real part of $\alpha$. We shall also adopt MATLAB-like convention to access the entries of vectors and matrices. $i : j$ is the set of integers from $i$ to $j$ inclusive and $i : i = \{i\}$. For a vector $u$ and a matrix $X$, $u_{(j)}$ is $u$'s $j$th entry, $X_{(i,j)}$ is $X$'s $(i,j)$th entry; $X$'s submatrices $X_{(k:\ell,i:j)}$, $X_{(k:\ell,:)}$, and $X_{(:,i:j)}$ consist of intersections of row $k$ to row $\ell$ and column $i$ to column $j$, row $k$ to row $\ell$, and column $i$ to column $j$, respectively.

## 2. ADI for Sylvester equations

As has been shown in [31] (more detailed in [30]) for given two sets of parameters $\{\alpha_i\}$ and $\{\beta_i\}$, the factored Alternating-Directional-Implicit (fADI) iteration for iteratively solving (1.1) proceeds as follows:

For $k = 0, 1, \ldots,$

$$Z_k = \begin{pmatrix} Z^{(1)} & Z^{(2)} & \cdots & Z^{(k)} \end{pmatrix}, \quad \text{with} \quad \begin{cases} Z^{(1)} & = & (A - \beta_1 I)^{-1} G, \\ Z^{(i+1)} & = & (A - \alpha_i I)(A - \beta_{i+1} I)^{-1} Z^{(i)} \\ & = & Z^{(i)} + (\beta_{i+1} - \alpha_i)(A - \beta_{i+1} I)^{-1} Z^{(i)}, \end{cases} \tag{2.1}$$

and

$$Y_k = \begin{pmatrix} Y^{(1)} & Y^{(2)} & \cdots & Y^{(k)} \end{pmatrix}, \quad \text{with} \quad \begin{cases} Y^{(1)^*} & = & F^*(B - \alpha_1 I)^{-1}, \\ Y^{(i+1)^*} & = & Y^{(i)^*}(B - \alpha_{i+1} I)^{-1}(B - \beta_i I) \\ & = & Y^{(i)^*} + (\alpha_{i+1} - \beta_i) Y^{(i)^*}(B - \alpha_{i+1} I)^{-1}, \end{cases} \tag{2.2}$$

and

$$X_k = Z_k D_k Y_k^*, \qquad D_k = \text{diag}\left( (\beta_1 - \alpha_1) I_r, \ldots, (\beta_k - \alpha_k) I_r \right). \tag{2.3}$$

Formulas (2.1)–(2.3) yield a new fADI which is a natural extension of CF-ADI [20] and LR-ADI [22,23] for stable Lyapunov equations.

---

[1] The parameters for the case were also made available by Wachspress in 2000.

**Algorithm 1** (*fADI for Sylvester Equation $AX - XB = GF^*$*).

**Input**:　(a) $A_{(m \times m)}$, $B_{(n \times n)}$, $G_{(m \times r)}$, and $F_{(n \times r)}$;
　　　　(b) ADI shifts $\{\beta_1, \beta_2, \ldots\}$, $\{\alpha_1, \alpha_2, \ldots\}$;
　　　　(c) $k$, the number of ADI steps;
**Output:**　$Z_{(m \times kr)}$, $D_{(kr \times kr)}$, and $Y_{(n \times kr)}$ such that $ZDY^*$ approximately
　　　　solves Sylvester equation $AX - XB = GF^*$;
　　　　1. $Z_{(:,1:r)} = (A - \beta_1 I)^{-1} G$; $(Y^*)_{(1:r,:)} = F^*(B - \alpha_1 I)^{-1}$;
　　　　2. **for** $i = 1, 2, \ldots, k$ **do**
　　　　3.　　$Z_{(:,ir+1:(i+1)r)} = Z_{(:,(i-1)r+1:ir)}$
　　　　　　　　　　$+ (\beta_{i+1} - \alpha_i)(A - \beta_{i+1}I)^{-1} Z_{(:,(i-1)r+1:ir)}$;
　　　　4.　　$(Y^*)_{(ir+1:(i+1)r,:)} = (Y^*)_{((i-1)r+1:ir,:)}$
　　　　　　　　　　$+ (\alpha_{i+1} - \beta_i) (Y^*)_{((i-1)r+1:ir,:)} (B - \alpha_{i+1}I)^{-1}$;
　　　　5. **end for;**
　　　　6. $D = \mathrm{diag}\left((\beta_1 - \alpha_1)I_r, \ldots, (\beta_k - \alpha_k)I_r\right)$.

**Remark 1.** For general dense $A$ and $B$, Algorithm 1 as is not appealing computationally because a linear system with a shifted $A$ costs $O(m^3)$ while a linear system with a shifted $B$ costs $O(n^3)$. That makes it no better than, e.g., the standard Bartels–Stewart algorithm [10] or the Hessenberg–Schur method [8,11]. For large $m$ and $n$ which is the focus of this article, often $A$ and $B$ either are very sparse, meaning only a small percentage of their entries are nonzero, or have certain structures, e.g., narrow banded, so that the costs for solving the linear systems may likely be $O(m^2)$ and $O(n^2)$, or sometimes even less $O(m)$ and $O(n)$. For modest $m$ and $n$, some pre-processing can be done to bring down the cost of each fADI step to $O(m^2 + n^2)$ by first performing Hessenberg reductions on $A$ and $B$, a standard practice for computing the Schur form of a nonsymmetric matrix [37]. This is done via unitary transformations and thus stable. As Wachspress pointed out to the authors, it is also possible to reduce $A$ and $B$ to very narrow banded matrices by general similarity transformations but care must be taken to monitor the conditioning of the transformation matrices.

　　We also note that the $Z$- and $Y$-factors in Algorithm 1 can be computed in parallel.

## 3. A shift strategy

　　ADI shifts determine the speed of the convergence of the method. There are a number of strategies out there, and most of them are based on heuristic arguments, except in the Hermitian cases. In his thesis, Sabino [36] presented a quite complete review of the existing strategies. Since this paper, however, is not about looking for yet another shift strategy, for testing purpose we shall simply discuss an easily implementable extension of Penzl's [22,23] who did it for Lyapunov equations.

　　As has been emphasized in the introduction, our approach here is based on the following idea: try to solve Sylvester equation using any two sets of ADI parameters (we propose extension of Penzl's shifts) and then improve the obtained solution by performing a Galerkin-type projection via the row and column subspaces of the computed solutions.

　　When $A$ and $B$ are Hermitian (this is in fact true for normal $A$ and $B$), the optimal ADI parameters are solutions of the following ADI minimax problem for $k$ ADI steps with $\mathbb{E} = \mathrm{eig}(A)$ and $\mathbb{F} = \mathrm{eig}(B)$, where $\mathrm{eig}(\cdot)$ denotes the spectrum of a matrix.

$$
\begin{array}{|l|}
\hline
\textit{Find } \alpha_j \textit{ and } \beta_j, j = 1, \ldots, k, \textit{ such that} \\[2ex]
\qquad \min_{\substack{\alpha_i \in \mathbb{C} \\ \beta_j \in \mathbb{C}}} \max_{\substack{x \in \mathbb{E} \\ y \in \mathbb{F}}} \prod_{j=1}^{k} \left| \frac{(x - \alpha_j)(y - \beta_j)}{(x - \beta_j)(y - \alpha_j)} \right|. \\
\hline
\end{array}
\tag{3.1}
$$

In practice since $\mathrm{eig}(A)$ and $\mathrm{eig}(B)$ are not known *a priori*, $\mathbb{E}$ and $\mathbb{F}$ are often replaced by intervals that contain the eigenvalues of $A$ and $B$, respectively. In the case for Lyapunov equations, $B = -A^*$, $\beta_j = -\bar{\alpha}_j$ (the complex conjugate of $\alpha_j$), and $\mathbb{F} = -\mathbb{E}$, Problem (3.1) reduces to

$$
\begin{array}{|l|}
\hline
\textit{Find } \alpha_j, j = 1, \ldots, k, \textit{ such that} \\[2ex]
\qquad \min_{\alpha_i \in \mathbb{C}} \max_{x \in \mathbb{E}} \prod_{j=1}^{k} \left| \frac{x - \alpha_j}{x + \bar{\alpha}_j} \right|. \\
\hline
\end{array}
\tag{3.2}
$$

Regardless of whether $A$ is Hermitian or not, for stable Lyapunov equations Penzl [23] proposed a heuristic shift-selection strategy by solving a much simplified (3.2): Find $\alpha_j, j = 1, \ldots, k$, such that

$$
\min_{\alpha_i \in \mathbb{E}} \max_{x \in \mathbb{E}} \prod_{j=1}^{k} \left| \frac{x - \alpha_j}{x + \bar{\alpha}_j} \right|
\tag{3.3}
$$

with $\mathbb{E}$ set to be a collection of certain estimates of the extreme eigenvalues of $A$. The strategy usually works very well. In obtaining $\mathbb{E}$, Penzl proposed to run a pair of Arnoldi processes. The first process delivers $k_+$ Ritz values that tend to approximate well "outer" eigenvalues, which are generally not close to the origin. The second process is used to get $k_-$ Ritz values to approximate those eigenvalues near the origin. His algorithm then chooses a set of shift parameters out of $\mathbb{E}$ by solving (3.3). The shifts delivered by the heuristic are ordered in such a way that shifts, which should reduce the ADI error most, are applied first.

Penzl's strategy can be naturally extended to the case for Sylvester equations. Now we need to compute two sets $\{\alpha_1, \ldots, \alpha_k\}$ and $\{\beta_1, \ldots, \beta_k\}$ of presumed good shift parameters. We start by generating two discrete sets $\mathbb{E}$ and $\mathbb{F}$ which "well" approximates parts of the spectra of $A$ and $B$, respectively, and then solve a much simplified (3.1): Find $\alpha_j$ and $\beta_j$, $j = 1, \ldots, k$, such that

$$\min_{\substack{\alpha_i \in \mathbb{E} \\ \beta_j \in \mathbb{F}}} \max_{\substack{x \in \mathbb{E} \\ y \in \mathbb{F}}} \prod_{j=1}^{k} \left| \frac{(x - \alpha_j)(y - \beta_j)}{(x - \beta_j)(y - \alpha_j)} \right|. \tag{3.4}$$

Again the selected shifts are ordered in such a way that shifts, which should reduce the ADI error most, are applied first. This is summarized in Algorithm 2.

**Algorithm 2** (*ADI parameters by Ritz values (ADIpR)*).

**Input**: $A$, $F$, $B$, $G$, $k$;
**Output:** ADI parameters $\{\alpha_1, \ldots, \alpha_k\}$ and $\{\beta_1, \ldots, \beta_k\}$;

1. Run Arnoldi process with $A$ on $G$ to give the set $\mathbb{E}_A^+$ of Ritz values;
2. Run Arnoldi process with $A^{-1}$ on $G$ to give the set $\mathbb{E}_A^-$ of Ritz values;
3. $\mathbb{E} = \mathbb{E}_A^+ \cup (1/\mathbb{E}_A^-)$;
4. Run Arnoldi process with $B^*$ on $F$ to give the set $\mathbb{F}_B^+$ of Ritz values;
5. Run Arnoldi process with $B^{-*}$ on $F$ to give the set $\mathbb{F}_B^-$ of Ritz values;
6. $\mathbb{F} = \text{conj}(\mathbb{F}_B^+) \cup \text{conj}(1/\mathbb{F}_B^-)$;
7. Set $\{\alpha_1, \beta_1\} = \arg \min_{\substack{\alpha \in \mathbb{E} \\ \beta \in \mathbb{F}}} \max_{\substack{x \in \mathbb{E} \\ y \in \mathbb{F}}} \left| \frac{(x-\alpha)(y-\beta)}{(x-\beta)(y-\alpha)} \right|$;
8. For $i = 2, \ldots, k$ do
9.     Set $\{\alpha_i, \beta_i\} = \arg \min_{\substack{\alpha \in \mathbb{E}' \\ \beta \in \mathbb{F}'}} \max_{\substack{x \in \mathbb{E} \\ y \in \mathbb{F}}} \left| \frac{(x-\alpha)(y-\beta)}{(x-\beta)(y-\alpha)} \right| \prod_{j=1}^{i-1} \left| \frac{(x-\alpha_j)(y-\beta_j)}{(x-\beta_j)(y-\alpha_j)} \right|$,

    where $\mathbb{E}'$ is $\mathbb{E}$ with $\alpha_1, \ldots, \alpha_{i-1}$ deleted, and similarly for $\mathbb{F}'$;
10. EndDo.

For more details about its efficient implementation, the reader is referred to [30].

**Remark 2.** Recently, Wachspress in [38] improved spectral alignment. He showed that the crucial values for determination of a proper set of ADI parameters are the minimum real part, the maximum real part, and the maximum angle for each spectrum. This can be done with the precise knowledge of the spectra. On the other hand as we have already mentioned in the Remark 1 it is possible, for modest $m$ and $n$, to reduce $A$ and $B$ to very narrow banded matrices by general similarity transformations but care must be taken to monitor the conditioning of the transformation matrices. Since this reduction enhances accurate eigenvalue estimation with the aid of double-implicit LR reduction with bounded pivots to maintain low bandwidth. The LR approach could replace Arnoldi in Algorithm 2 with shifts chosen to reveal the crucial eigenvalues. This could be interesting problem for further studies.

## 4. Projection ADI subspace methods for Sylvester equation

Given parameters $\{\alpha_i\}$ and $\{\beta_i\}$, we define the $k$th *ADI column subspace* to be the column space of the $k$th ADI solution $X_k = Z_k D_k Y_k^*$ and the $k$th *ADI row subspace* to be the row space of $X_k^*$. Equivalently the $k$th ADI column subspace is the column space of $Z_k$, and the $k$th ADI row subspace is the row space of $Y_k^*$.

Our numerical experiments strongly suggest often these ADI subspaces are quite good in the sense that the ADI column subspaces come very close to the column space of $X$, the exact solution, and ADI row subspaces come very close to the row space of $X$. This is true even for not so good parameters $\{\alpha_i\}$ and $\{\beta_i\}$. Our numerical experiments also suggest that *one* single poor shift can effectively offset all previous good shifts and thus degrade ADI approximations enormously for the next many iterations.

Given that it is so hard to select optimal, sometime even decent, parameters in general for ADI solutions to be any good, perhaps we should seek instead solutions having form

$$\widetilde{X}_k = U_k W_k V_k^* \tag{4.1}$$

under the Galerkin condition or the minimal residual condition, where $U_k$ has the same columns space as $Z_k$ ($X_k$) and $V_k^*$ has the same row space as $Y_k^*$ ($X_k$). We call a method as such a *projection ADI subspace method*. Since $Z_k$ and $Y_k$ are computed one block at a time by Algorithm 1 from the very previous blocks, $U_k$ and $V_k$ can be computed along the way, by, e.g., the (modified) Gram–Schmidt orthogonalization process as soon as a new $Z$-block or $Y$-block becomes available. Doing so leads to $U_k$ and $V_k$ with orthonormal columns.

The idea of using Galerkin projection or minimizing the residual is not new. What that *is* new here is our choices of projection subspaces. Previously it was used when columns of $U_k$ and $V_k$ span a Krylov subspace of $A$ on $G$ and a Krylov subspace of $B^*$ on $F^*$, respectively [15,16,39] and more recently for Lyapunov equations for which $U_k = V_k$ spans a direct sum of Krylov subspaces of $A$ on $G$ and $A^{-1}$ on $G$ [17].

### 4.1. Galerkin projection

Suppose $U_k$ and $V_k$ have orthonormal columns. Let residual $R_k = A\widetilde{X}_k - \widetilde{X}_k B - C$ for an approximation solution $\widetilde{X}_k$. The Galerkin condition enforces $U_k^* R_k V_k = 0$. Thus

$$(U_k^* A U_k)W_k - W_k(V_k^* B V_k) = U_k^* C V_k \tag{4.2}$$

which is a Sylvester equation but of a much smaller size and can be solved by, e.g., Bartel–Stewart algorithm [10], or Golub–Nash–Van Loan algorithm [11].

Note that $U_k$ and $V_k$ do not necessarily have to have the same number of columns. When they do not, $W_k$ will not be a square matrix.

### 4.2. A minimal residual method

The minimal residual condition requires to solve

$$\min_{W_k} \|R_k\|_F \equiv \min_{W_k} \left\| A(U_k W_k V_k^*) - (U_k W_k V_k^*)B - C \right\|_F. \tag{4.3}$$

It turns out going from the simple Galerkin projection to this minimal residual condition is utterly nontrivial computationally. The novel idea due to Hu and Reichel [15, p. 293] can be modified to work, thanks to Theorem 4.1 below. But the amount of increased work makes it less attractive. Nevertheless, we still present Theorem 4.1 which may be of independent interest of its own right. Adopt the notation of Section 2 in its entirety. By (2.1) and (2.2), the $k$th ADI column and row spaces are

$$\mathscr{C}_k \stackrel{\text{def}}{=} \text{colspan}\{Z^{(1)}, Z^{(2)}, \dots, Z^{(k)}\}, \qquad \mathscr{R}_k \stackrel{\text{def}}{=} \text{rowspan}\{Y^{(1)*}, Y^{(2)*}, \dots, Y^{(k)*}\},$$

respectively.

**Theorem 4.1.** *We have for $i \geq 1$*

$$AZ^{(i)} = G + \prod_{j=1}^{i-1}(\beta_j - \alpha_j)Z^{(j)} + \beta_i Z^{(i)}, \tag{4.4}$$

$$Y^{(i)*}B = F^* + \prod_{j=1}^{i-1}(\alpha_j - \beta_j)Y^{(j)*} + \alpha_i Y^{(i)*}, \tag{4.5}$$

*where $\prod_{j=1}^{0}(\cdots)$ is taken to be 0. Therefore*

$$A\mathscr{C}_k \subseteq \text{colspan}\{G, Z^{(1)}, Z^{(2)}, \dots, Z^{(k)}\} = \text{colspan}\{G\} + \mathscr{C}_k, \tag{4.6}$$

$$\mathscr{R}_k B \subseteq \text{rowspan}\{F^*, Y^{(1)*}, Y^{(2)*}, \dots, Y^{(k)*}\} = \text{rowspan}\{F^*\} + \mathscr{R}_k. \tag{4.7}$$

**Proof.** By (2.1), we have

$$
\begin{aligned}
AZ^{(1)} &= A(A - \beta_1 I)^{-1}G \\
&= G + \beta_1(A - \beta_1 I)^{-1}G \\
&= G + \beta_1 Z^{(1)},
\end{aligned}
$$

$$
\begin{aligned}
AZ^{(i+1)} &= AZ^{(i)} + (\beta_{i+1} - \alpha_i)A(A - \beta_{i+1}I)^{-1}Z^{(i)} \\
&= AZ^{(i)} + (\beta_{i+1} - \alpha_i)Z^{(i)} + (\beta_{i+1} - \alpha_i)\beta_{i+1}(A - \beta_{i+1}I)^{-1}Z^{(i)} \\
&= AZ^{(i)} + (\beta_{i+1} - \alpha_i)Z^{(i)} + \beta_{i+1}(Z^{(i+1)} - Z^{(i)}) \\
&= AZ^{(i)} - \alpha_i Z^{(i)} + \beta_{i+1}Z^{(i+1)} \\
&= AZ^{(i-1)} - \alpha_{i-1}Z^{(i-1)} + \beta_i Z^{(i)} - \alpha_i Z^{(i)} + \beta_{i+1}Z^{(i+1)} \\
&= \cdots \\
&= AZ^{(1)} - \alpha_1 Z^{(1)} + \prod_{j=2}^{i}(\beta_j - \alpha_j)Z^{(j)} + \beta_{i+1}Z^{(i+1)} \\
&= G + \prod_{j=1}^{i}(\beta_j - \alpha_j)Z^{(j)} + \beta_{i+1}Z^{(i+1)}
\end{aligned}
$$

which proves (4.4). Similarly

$$
\begin{aligned}
Y^{(1)*}B &= F^*(B - \alpha_1 I)^{-1}B \\
&= F^* + \alpha_1 F^*(B - \alpha_1 I)^{-1} \\
&= F^* + \alpha_1 Y^{(1)*}, \\
Y^{(i+1)*}B &= Y^{(i)*}B + (\alpha_{i+1} - \beta_i)Y^{(i)*}(B - \alpha_{i+1}I)^{-1}B \\
&= Y^{(i)*}B + (\alpha_{i+1} - \beta_i)Y^{(i)*} + (\alpha_{i+1} - \beta_i)\alpha_{i+1}Y^{(i)*}(B - \alpha_{i+1}I)^{-1} \\
&= Y^{(i)*}B + (\alpha_{i+1} - \beta_i)Y^{(i)*} + \alpha_{i+1}(Y^{(i+1)*} - Y^{(i)*}) \\
&= Y^{(i)*}B - \beta_i Y^{(i)*} + \alpha_{i+1}Y^{(i+1)*} \\
&= F^* + \prod_{j=1}^{i}(\alpha_j - \beta_j)Y^{(j)*} + \alpha_{i+1}Y^{(i+1)*}
\end{aligned}
$$

which proves (4.5).  □

The objective function in (4.3) is the Frobenius norm of an $m \times n$ matrix. Recall that the Sylvester equations we are interested have large $m$ and $n$. Potentially (4.3) is as difficult as the original equation itself. Using the results of Theorem 4.1, we can reduced the size of the problem to at most $(k + 1)r \times (k + 1)r$. We shall now explain how. Assume that both $U_k$ and $V_k$ have orthonormal columns to begin with. Now orthogonalize $G$ against the columns of $U_k$, and $F$ against the columns of $V_k$ to get $(U_k, \widehat{U})$ and $(V_k, \widehat{V})$, both having orthonormal columns. It can be seen that both $\widehat{U}$ and $\widehat{V}$ have no more than $r$ columns. Theorem 4.1 implies

$$
AU_k = (U_k, \widehat{U})A_k, \qquad V_k^*B = B_k(V_k, \widehat{V})^*
$$

for some matrices $A_k$ and $B_k$. Then

$$
A(U_k W_k V_k^*) - (U_k W_k V_k^*)B - C = (U_k, \widehat{U})A_k W_k V_k^* - U_k W_k B_k(V_k, \widehat{V})^* - C
$$

from which one can see that the solution $W_k$ of (4.3) is the same as that of

$$
\min_{W_k} \left\| A_k W_k(I, 0) - \binom{I}{0} W_k B_k - (U_k, \widehat{U})^*G[(V_k, \widehat{V})^*F]^* \right\|_F, \tag{4.8}
$$

a much smaller problem than (4.3). This problem can be solved by borrowing the idea of Hu and Reichel [15, p. 293]. But still its cost of doing so is much higher than solving (4.2) as the result of the simple Galerkin projection, nonetheless.

## 5. Application to Lyapunov equation

fADI in Section 2 is a natural extension of the LR-CF ADI [20,22,23] for the Lyapunov Equation

$$
AX + XA^* = C, \tag{5.1}
$$

where $A$, $C$, and unknown $X$ are all $n \times n$, and $C$ is Hermitian. Since, Lyapunov equation (5.1) is a special case of Sylvester equation (1.1) with $B = -A^*$, previous developments apply upon substituting $B = -A^*$ and $\beta_i = -\bar{\alpha}_i$, and most expressions can be much simplified, too.

In the case of Lyapunov equation it holds $Y^{(k)} = Z^{(k)}$, thus instead of (2.1) and (2.2) we have

$$
Z_k = \begin{pmatrix} Z^{(1)} & Z^{(2)} & \cdots & Z^{(k)} \end{pmatrix}, \quad \text{with} \begin{cases} Z^{(1)} &= (A + \bar{\alpha}_1 I)^{-1}G, \\ Z^{(i+1)} &= (A - \alpha_i I)(A + \bar{\alpha}_{i+1}I)^{-1}Z^{(i)} \\ &= Z^{(i)} - (\bar{\alpha}_{i+1} + \alpha_i)(A + \bar{\alpha}_{i+1}I)^{-1}Z^{(i)}, \end{cases} \tag{5.2}
$$

while (2.3) is given by

$$X_k = Z_k D_k Z_k^*, \qquad D_k = -2 \text{diag} \left( \Re(\alpha_1) I_r, \ldots, \Re(\alpha_k) I_r \right). \tag{5.3}$$

Based on (5.2) and (5.3), an fADI for Lyapunov equation $AX + XA^* + GG^* = 0$ is obtained as in Algorithm 3.

**Algorithm 3** (fADI for Lyapunov Equation $AX + XA^* + GG^* = 0$).

**Input**:    (a) $A_{(m \times m)}$, and $G_{(m \times r)}$;
          (b) ADI shifts $\{\alpha_1, \alpha_2, \ldots\}$;
          (c) $k$, the number of ADI steps;
**Output:**  $Z_{(m \times kr)}$ and $D_{(kr \times kr)}$ such that $ZDZ^*$ approximately
           solves Lyapunov equation $AX + XA^* + GG^* = 0$;
          1.  $Z_{(:,1:r)} = (A + \bar{\alpha}_1 I)^{-1} G$;
          2.  **for** $i = 1, 2, \ldots, k$ **do**
          3.      $Z_{(:,ir+1:(i+1)r)} = Z_{(:,(i-1)r+1:ir)} - (\bar{\alpha}_{i+1} + \alpha_i)(A + \bar{\alpha}_{i+1})^{-1} Z_{(:,(i-1)r+1:ir)}$;
          5.  **end for;**
          6.  $D = -2 \, \text{diag} \left( \Re(\alpha_1) I_r, \ldots, \Re(\alpha_k) I_r \right)$.

For a stable Lyapunov equation, this essentially gives the so-called Cholesky Factor ADI (CF-ADI) of Li and White [20] and Low Rank ADI of Penzl [22], except that in CF-ADI/LR-ADI matrices $D_i$ are embedded into $Z_i$. The difference is that here we have a matrix $D$. An advantage of doing so is that the algorithm no longer requires all $\Re(\alpha_i) > 0$, as must have in [20,22]. Thus Algorithm 3 has a larger domain of applicability than its earlier versions.

## 6. Numerical experiments

In this section, we shall report several numerical examples to demonstrate that the Galerkin projection via ADI subspaces can lead to more accurate solutions than ADI alone.

**Example 6.1.** This is essentially [40, Example 1], except for $C$ which will be set to some random rank-1 matrix. Depending on parameters $a$, $b$, $s$ and the dimension $n$, matrices $A$, $B$, and $C$ are generated as follows. First, set

$$\widehat{A} = \text{diag}(-1, -a, -a^2, \ldots, -a^{n-1}),$$
$$\widehat{B} = \text{diag}(1, b, b^2, \ldots, b^{n-1}),$$
$$\widehat{C} = \widehat{G}\widehat{F}^*,$$

where $\widehat{G}$ and $\widehat{F}$ are $n \times 1$ and generated randomly as by $\texttt{randn}(n, 1)$ in MATLAB. Parameters $a$ and $b$ regulate the distribution of the spectra of $A$ and $B$, respectively, and therefore their separation. The entries of the solution matrix to $\widehat{A}\widehat{X} - \widehat{X}\widehat{B} = \widehat{C}$ are then given by

$$\widehat{X}_{(i,j)} = \frac{\widehat{C}_{(i,j)}}{\widehat{A}_{(i,i)} - \widehat{B}_{(j,j)}}.$$

Next we employ a transformation matrix to define

$$A = T^{-\mathsf{T}}\widehat{A}T^{\mathsf{T}}, \qquad B = T\widehat{B}T^{-1}, \qquad G = T^{-\mathsf{T}}\widehat{G}, \qquad F = \widehat{F}T^{-1},$$

where $T = H_2 S H_1 \in \mathbb{C}^{n \times n}$ is defined through

$$H_1 = I_n - \frac{2}{n} h_1 h_1^{\mathsf{T}}, \qquad h_1 = (1, 1, \ldots, 1)^{\mathsf{T}},$$
$$H_2 = I_n - \frac{2}{n} h_2 h_2^{\mathsf{T}}, \qquad h_2 = (1, -1, \ldots, (-1)^{n-1})^{\mathsf{T}},$$
$$S = \text{diag}(1, s, \ldots, s^{n-1}).$$

The scalar $s$ is used here to regulate the conditioning of $T$. Because of the way they are constructed, each linear system with shifted $A$ or $B$ costs $O(n)$ flops to solve. In all our tests reported here, $k = 25$ and $n = 500$. We tested Algorithms 1 and 2 on two sets of parameter values:

$$a = 1.03, \qquad b = 1.008, \qquad s = 1.001; \tag{6.1}$$
$$a = 1.03e^{i\theta}, \qquad b = 1.008e^{i\theta}, \qquad s = 1.001, \tag{6.2}$$

where $i = \sqrt{-1}$ and $\theta = \pi/(2n)$. The values given in (6.1) were the ones used in [40]. In applying Algorithm 2, each Arnoldi run takes 35 steps and 17 best Ritz values are taken, and thus both $\mathbb{E}$ and $\mathbb{F}$ have 34 values among which 25 are selected in
**Fig. 6.1.** Relative residual errors for ADI solutions and solutions by Galerkin projection via ADI subspaces for two different runs for Example 6.1 with (6.1).

**Fig. 6.2.** Relative residual errors for ADI solutions and solutions by Galerkin projection via ADI subspaces for two different runs for Example 6.1 with (6.2).

the end. Our fADI produces an approximation $X_k = Z_k D_k Y_k^*$, along with intermediate approximations $X_i = Z_i D_i Y_i^*$ for $i \leq k$. For two runs with different random $F$ and $G$, Figs. 6.1 and 6.2 plot the relative residual errors

$$\frac{\|AX_i - X_i B - GF^*\|_F}{\|GF^*\|_F}$$

(marked as "ADI"), as well as the relative residual errors for the approximations $U_i W_i V_i^*$ by Galerkin projection (4.2) (marked as "ADI + Galerkin"). We have run tests on each parameter set many times with different random $F$ and $G$, and the residual behaviors are all similar to those plotted in Figs. 6.1 and 6.2. In both figures, Galerkin projection via ADI subspaces produces better approximations after $i \geq 7$ and the improvements are up to more than 2 decimal digits.   ◇

**Example 6.2.** Chahlaoui and Van Dooren [41] compiled a collection of benchmark examples for model reduction. Except those for descriptor systems, these examples give rise to Lyapunov equations $AX + XA^* + GG^* = 0$. Simplified versions of
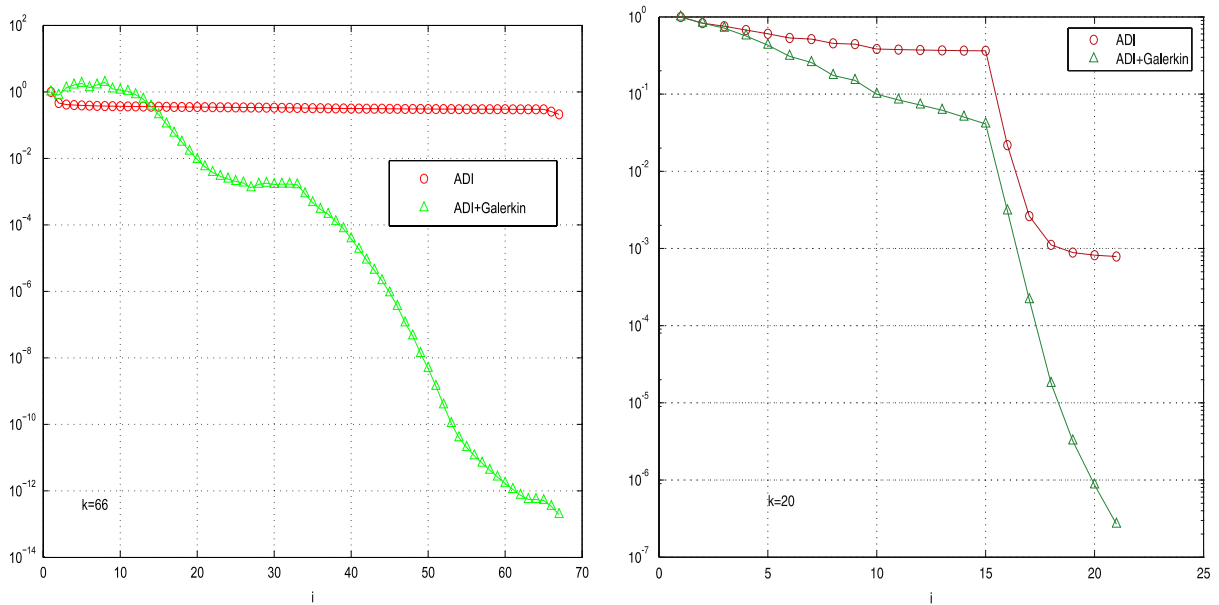

**Fig. 6.3.** Relative residual errors for ADI solutions and solutions by Galerkin projection via ADI subspaces. *Left*: FOM in [41]; *Right*: HEAT in [41].

Algorithms 1 and 2 upon substituting $B = -A^*$ and $F = -G^*$ can be applied. We have tested ADI and Galerkin projection via ADI subspaces on these equations, and found out both performs badly when $A$ is highly non-normal in the sense that $\|A\|_F^2$ and $\|A\|_F^2 - \sum_j |\lambda_j|^2$ are of the same magnitude and $\sum_j |\lambda_j|^2 \ll \|A\|_F^2$, where $\{\lambda_j\}$ consists of all $A$'s eigenvalues. In the collection, there are two other examples whose $A$ are in fact normal, i.e., $\|A\|_F^2 = \sum_j |\lambda_j|^2$. We now report our numerical results on them. The first example is FOM: $A = \mathrm{diag}(A_1, A_2, A_3, A_4)$ with

$$A_1 = \begin{pmatrix} -1 & 100 \\ -100 & -1 \end{pmatrix}, \qquad A_2 = \begin{pmatrix} -1 & 200 \\ -200 & -1 \end{pmatrix}, \qquad A_3 = \begin{pmatrix} -1 & 400 \\ -400 & -1 \end{pmatrix},$$

$A_4 = \mathrm{diag}(-1, -2, \ldots, -1000)$, and $G = (\underbrace{10, \ldots, 10}_{6}, \underbrace{1, \ldots, 1}_{1000})^\mathrm{T}$. So $n = 1006$ and each linear system with shifted $A$ or $A^*$ takes $O(n)$ flops to solve. Apply Algorithms 1 and 2 with $k = 66$, where for Algorithm 2, each Arnoldi run takes 76 steps and 38 best Ritz values are taken, and thus $\mathbb{E}$ has 76 values among which 66 are selected in the end. The left of Fig. 6.3 plots the relative residual errors for ADI solutions and solutions by Galerkin projection via ADI subspaces, as explained in Example 6.1. For this example, ADI barely does anything while projection ADI subspace method does extremely well.

The other example is from discretizing the 1D heat equation. $A$ is real symmetric tridiagonal. Thus each linear system with shifted $A$ or $A^*$ takes $O(n)$ flops to solve. The size of $A$ can be made as large as one wishes. As in [41], we take $n = 200$, and $A$ has diagonal entries $-808$ and off-diagonal entries 404, and all of $G$'s entries are zero, except $G_{(67)} = 1$. With $k = 20$ for Algorithm 2, each Arnoldi run takes 30 steps and 15 best Ritz values are taken, and thus $\mathbb{E}$ has 30 values among which 20 are selected in the end. The right of Fig. 6.3 plots the relative residual errors for ADI solutions and for solutions by Galerkin projection via projection ADI subspaces method.    ◇

**Example 6.3.** This is a Sylvester equation $AX - XB = GF^*$ with real symmetric $A$ and $B$, both taken from the Harwell–Boeing Collection. In fact, $A(675 \times 675)$ is NOS6 and $B(468 \times 468)$ is negative NOS5 from Set LANPRO.[2] $G$ and $F$ are taken to be random vectors. Sylvester equations so constructed are solely for our testing purpose because there is no physical background yet for combining the two matrices together in one Sylvester equation. Both $A$ and $B$ are sparse and in fact very narrow banded, and each linear system with shifted $A$ or $B$ costs $O(m)$ or $O(n)$ flops to solve, respectively.

Fig. 6.4 plots the relative residual errors for ADI solutions and solutions by Galerkin projection via ADI subspaces for $k = 34$ (*left*) and $k = 44$ (*right*) by applying Algorithms 1 and 2. For $k = 34$, in Algorithm 2 each Arnoldi run takes 44 steps and 22 best Ritz values are taken, and thus both $\mathbb{E}$ and $\mathbb{F}$ have 44 values among which 34 are selected in the end; and for $k = 44$, in Algorithm 2 each Arnoldi run takes 54 steps and 27 best Ritz values are taken, and thus both $\mathbb{E}$ and $\mathbb{F}$ have 54 values among which 44 are selected in the end.    ◇

## 7. Conclusions

We have presented a factored ADI for Sylvester equation $AX - XB = GF^*$, Lyapunov equation as a special case included. It is based on a set of formulas which generalize corresponding ones in the CF-ADI for Lyapunov equation. They enable one to compute the columns of the left factor and the rows of the right factor one block per step. We also demonstrate that often much more accurate solutions than the ADI solutions can be obtained by performing Galerkin projection using the column spaces and row spaces of the computed approximate solutions.
